PURPOSE. The International Myopia Institute (IMI) Yearly Digest highlights new research considered to be of importance since the publication of the first series of IMI white papers.

METHODS. A literature search was conducted for articles on myopia between 2019 and mid-2020 to inform definitions and classifications, experimental models, genetics, interventions, clinical trials, and clinical management. Conference abstracts from key meetings in the same period were also considered.

RESULTS. One thousand articles on myopia have been published between 2019 and mid-2020. Key advances include the use of the definition of premyopia in studies currently under way to test interventions in myopia, new definitions in the field of pathologic

Received: December 22, 2020

myopia, the role of new pharmacologic treatments in experimental models such as intraocular pressure-lowering latanoprost, a large meta-analysis of refractive error identifying 336 new genetic loci, new clinical interventions such as the defocus incorporated multisegment spectacles and combination therapy with low-dose atropine and orthokeratology (OK), normative standards in refractive error, the ethical dilemma of a placebo control group when myopia control treatments are established, reporting the physical metric of myopia reduction versus a percentage reduction, comparison of the risk of pediatric OK wear with risk of vision impairment in myopia, the justification of preventing myopic and axial length increase versus quality of life, and future vision loss.

CONCLUSIONS. Large amounts of research in myopia have been published since the IMI 2019 white papers were released. The yearly digest serves to highlight the latest research and advances in myopia.

Keywords: myopia, classification, definitions, high myopia, pathologic myopia, genetics, emmetropization, interventions, atropine, contact lenses, spectacles, orthokeratology, management guidelines, clinical trials, axial length, cycloplegia

The International Myopia Institute (IMI) consensus group was founded in 2015 by the late Professor Brien Holden (BHVI, Sydney) following the joint World Health Organization (WHO) and BHVI Meeting on Myopia held in Sydney. The IMI was formed to facilitate the sharing of evidence-based findings related to the worldwide significant increase of myopia with practitioners, researchers, and policy makers. The initial impetus for the IMI was to develop consensus definitions of myopia, high myopia, and pathologic myopia, as well as recommendations on treatment strategies to prevent myopia onset and to slow myopia progression, especially in low-income settings, and to promote basic and clinical research on myopia.¹

The subsequent International Myopia Conference Meeting (IMC) in 2015 further highlighted the need for a consensus group and led to the collaboration between the IMC and IMI, which resulted in the formation of the initial seven task forces that produced the first series of IMI white papers on myopia. Wolffsohn et al.¹ details the history of the IMI. This was a truly global collaborative effort, and today the IMI has over 130 experts involved in 13 taskforces. The first white papers were published in *Investigative Ophthalmology and Visual Science (IOVS)* in 2019, a process chaired by Professors Earl Smith, James Wolffsohn, and Serge Resnikoff and facilitated by Dr. Monica Jong.

Professor Serge Resnikoff accepted the role of chair of IMI in 2018, and since the publication of the first IMI white papers, IMI has pursued its mission to disseminate evidence-based information to advance research, education, and myopia management to prevent future myopia-related vision loss and blindness. Recent key achievements include the IMI definitions² being referenced at the ICD-11 Revision Technical meeting in 2019, the IMI white papers being referenced in the WHO World Report on Vision, clinical summaries derived from the IMI white papers being translated into 12 languages, dedicated sessions being included at key practitioner and scientific meetings, and five new 2021 IMI white papers published in this special issue of *IOVS*. Raising awareness for myopia and high myopia as a significant public health issue is an ongoing process involving the collective efforts of researchers, clinicians, industry, policy makers, and various groups that work with children. More voices calling for collective action are necessary to move this area forward and ensure the latest evidence-based practice.

A search of PubMed using the term “myopia” from 2019 to mid-2020 alone yielded almost 1000 peer-reviewed articles. In other words, almost 1000 articles have been published since the first series of IMI white papers (2019). This presents a daunting challenge in trying to keep up with the latest information. The yearly digest is a simple and convenient way for clinicians and researchers to access the recent highlights in myopia. The yearly digests are organized around six of the original seven IMI white papers. The taskforce members producing the digests were involved in the original IMI white papers and have curated between 3 and 10 of the most potentially impactful articles published in their area from 2019 to the mid-2020, with personal insights. Various online databases were searched from 2019 up to mid-2020, and notable conference presentations that featured myopia such as the IMC 2019, Tokyo Medical and Dental University, and the ARVO 2020 virtual meeting were included. The Yearly Digest updates readers in the key advances in myopia in the following sections until the next series of these IMI white papers are published:

- Defining and classifying myopia
- Experimental models of emmetropization and myopia
- Genetics of myopia
- Interventions for controlling myopia onset and progression
- Clinical myopia control trials and instrumentation
- Clinical management guidelines for myopia

IMI DIGEST 2021—DEFINING AND CLASSIFYING MYOPIA

The IMI “Defining and Classifying Myopia” white paper proposed definitions for myopia, high myopia, and pathologic myopia based on statistical analysis of thresholds used in the literature and clinical relevance (Table 1 and Table 2).² Previously, over 400 definitions had been used in the literature, and many different cutoffs for myopia and high myopia had been suggested. This caused some confusion for differentiating various grades of myopia, in particular for the delineation of high myopia and pathologic myopia.^{2,3} Standardizing definitions will ease evidence-based manage-

TABLE 1. Summary of Proposed General and Quantitative Thresholds for Myopia Adapted From IMI Defining and Classifying Myopia White Paper²

Term	Definition
Qualitative definitions	
Myopia	A refractive error in which rays of light entering the eye parallel to the optic axis are brought to a focus in front of the retina when ocular accommodation is relaxed. This usually results from the eyeball being too long from front to back but can be caused by an overly curved cornea or a lens with increased optical power, or both. It is also called near sightedness.
Axial myopia	A myopic refractive state primarily resulting from a greater than normal axial length.
Refractive myopia	A myopic refractive state that can be attributed to changes in the structure or location of the image forming structures of the eye (i.e., the cornea and lens).
Secondary myopia	A myopic refractive state for which a single, specific cause (e.g., drug, corneal disease, or systemic clinical syndrome) can be identified that is not a recognized population risk factor for myopia development.
Quantitative definitions	
Myopia	A condition in which the spherical equivalent refractive error of an eye is ≤ -0.50 D when ocular accommodation is relaxed.
Low myopia	A condition in which the spherical equivalent refractive error of an eye is ≤ -0.50 D and > -6.00 D when ocular accommodation is relaxed.
High myopia	A condition in which the spherical equivalent refractive error of an eye is ≤ -6.00 D when ocular accommodation is relaxed.
Premyopia	A refractive state of an eye of $\leq +0.75$ D and > -0.50 D in children where a combination of baseline refraction, age, and other quantifiable risk factors provide a sufficient likelihood of the future development of myopia to merit preventative interventions.

TABLE 2. Definitions for the Structural Complications of Myopia^{2,29}

Term	Definition
Descriptive definitions	
Pathologic myopia	Excessive axial elongation associated with myopia that leads to structural changes in the posterior segment of the eye (including posterior staphyloma, myopic maculopathy, and high myopia-associated optic neuropathy) and that can lead to loss of best-corrected visual acuity.
Myopic macular degeneration (MMD)	A vision-threatening condition occurring in people with myopia, usually high myopia that comprises diffuse or patchy macular atrophy with or without lacquer cracks, macular Bruch's membrane defects, choroidal neovascularization, and Fuchs spot.
Diagnostic subdivisions of MMD	
Myopic maculopathy	Category 0: no myopic retinal degenerative lesion. Category 1: tessellated fundus. Category 2: diffuse chorioretinal atrophy. Category 3: patchy chorioretinal atrophy. Category 4: macular atrophy. "Plus" features: lacquer cracks, myopic choroidal neovascularization, and Fuchs spot.
Presumed myopic macular degeneration	A person who has vision impairment and vision acuity that is not improved by pinhole, which cannot be attributed to other causes, and The direct ophthalmoscopy records a supplementary lens > -5.00 D and shows changes such as "patchy atrophy" in the retina or The direct ophthalmoscopy records a supplementary lens > -10.00 D.
Specific clinical conditions characteristic of pathologic myopia	
Myopic traction maculopathy (MTM)	A combination of macular retinoschisis, lamellar macula hole, and/or foveal RD (FRD) in highly myopic eyes attributable to traction forces arising from adherent vitreous cortex, epiretinal membrane, internal limiting membrane, retinal vessels, and posterior staphyloma.
Myopia-associated glaucoma-like optic neuropathy	Optic neuropathy characterized by a loss of neuroretinal rim and enlargement of the optic cup, occurring in highly myopic eyes with a secondary macrodisc or parapapillary delta zone at a normal intraocular pressure.

ment of myopia and improve comparability of research outcomes. Since the publication of the IMI white paper on the myopia definitions, several studies have been published and selected here for commentary. These studies further highlight the need for standardization of the myopia definitions and show that definitions may be selected based on the relevant population and what is being evaluated as

an outcome. In addition to defining thresholds for myopia and pathologic myopia as a structural and not a refractive concept, a range of other terms were defined such as premyopia, secondary myopia, myopic traction maculopathy (MTM), and myopia-associated glaucoma-like optic neuropathy (MAGON) (further discussed in the IMI 2021 white paper: "IMI Pathologic Myopia"⁴). These terms are

starting to become more widely used and are further discussed below.

Myopia Thresholds

In relation to the standardization of refractive thresholds, several articles have explicitly cited the proposed standards.^{5,6} The need for standardization of definitions is highlighted by the continued publication of papers with varying definitions for high myopia.⁷ For example, a recent refractive surgery study defined a threshold for high myopia at -9.00 D.⁸ This paper, like many others, also highlighted the issue of the inconsistent use of the mathematical symbols for “less than” in relation to myopia, in that extremely high myopia was described as ≥ -9.00 D, but the context indicates that this was intended to mean more myopic than -9 D, rather than a refractive error ≥ -9.00 D. Another recent paper defined high myopia as “as the presence of a highly negative refractive error (>-6.00 to -8.00 D),” again using the mathematical symbol “ $>$ ” to mean “more myopic” when mathematically, it should be written as “ $<$ ” to indicate a more negative value and more myopia.⁹ The IMI definitions and classifications white paper² proposed that mathematical symbols should be used in a strict mathematical sense for consistency and that words be used where potential ambiguity arises (e.g., “more than 6.00 D of myopia” or “more myopic² than -6.00 D”).

Achieving complete consistency in reporting refractive errors is unlikely to be achieved in the short term. One suggestion in the IMI white paper² for reporting standards for myopia studies was that when different thresholds are used to better suit the research question, a sensitivity analysis should be performed at the chosen and standardized thresholds (i.e., spherical equivalent refraction ≤ -0.5 for myopia and ≤ -6.0 D for high myopia). This would be invaluable when it comes to comparing studies or performing meta-analyses. The value of this approach has been demonstrated in a paper published prior to the IMI report¹⁰ and supported in a paper published in 2020.¹¹ The cutoff values for myopia have a strong effect on the estimated prevalence of myopia and high myopia in population-based studies. For example, in the study by Parssinen and Kauppinen,¹² defining high myopia as a spherical equivalent refraction < -6.00 D in the right eye or by a spherical equivalent of ≤ -6.00 D or ≤ -5.00 D in either eye was associated with a myopia prevalence of 24%, 32% and 52%, respectively.

The recent publication of normative standards for refractive errors is also a step forward. San-Diez et al.¹³ reported axial length growth curves for Chinese children for estimating the risk of myopia, based on age, gender, the axial length/corneal radius ratio, and spherical refractive error. The growth curves were based on a data set from 12,554 children aged 5 to 16 years from Wuhan, China. Compared with the axial length growth curves for European children of the same age,^{13b} the Chinese children had significantly longer axial lengths. San-Diez and colleagues¹³ used a threshold of -5.00 D, but this study was initiated prior to the publication of the IMI white paper.² The definition of centile-based standards to refraction offers a rational basis for an age-adjusted definition of high myopia in children and adolescents, in whom the development of high myopia in adulthood is likely or very likely. Refraction reference curves in European children have also been published but were noncycloplegic.¹⁴

More longitudinal studies will be needed to validate these approaches.

In the IMI definitions white paper,² the proposed definition of myopia did not stipulate cycloplegia as a requirement but included the caveat “when ocular accommodation is relaxed” (Table 1). This was intentional to avoid potentially invalidating many epidemiologic studies in adults. Cycloplegia remains the gold standard in studies of refractive error in children,¹⁵ but in some settings, for example, school screenings, cycloplegia can be impractical, but the data are still useful (covered in detail in the “IMI Clinical Myopia Control Trials and Instrumentation” white paper).¹⁶ From a functional point of view, the various degrees of myopia may be defined by the uncorrected visual acuity of the respective refractive error. Introducing unaided distance visual acuity criteria could be useful to avoid overdiagnosing myopia due to instrument myopia when cycloplegia is not used.¹⁷

Other Definitions: Premyopia and Secondary Myopia

The concept of premyopia has emerged over the past few years, and the IMI proposed a practical definition of this concept (Table 1). Several clinical trials, notably the ATOM3 study from Singapore (NCT03140358, <https://clinicaltrials.gov/ct2/show/NCT03140358>), are currently recruiting premyopes to test whether atropine can delay or prevent myopia onset. Premyopia is now also being discussed in the context of a comprehensive approach to myopia progression management.¹⁸ Secondary myopia is a potentially useful concept but remains rarely used in this field, despite being a widely adopted term in other conditions (e.g., glaucoma). It has appeared recently in several publications as an exclusion criterion^{19,20} and in a review on the perennial “nature versus nurture” question.²¹

Pathologic Myopia

In relation to terminology and definitions, the area that remains in greatest flux is the concept of pathologic myopic. New classifications are still being proposed, and it is likely to be some time until a clear consensus emerges in this area.⁹ Rather than a refractive definition, the concept of pathologic myopia was defined in purely structural terms as a set of complications that arise from high myopia with increasing age.² The understanding of structural complications and their visual implications continues to evolve.²² Several recent papers provide excellent data on the risk of such complications and the impact on vision.^{23,24} Although high myopia-related ocular complications are recognized to increase with age, particularly after age 50 years, these complications are now also being recognized in highly myopic children.²⁵ The continual refinement of optical coherence tomography (OCT) will undoubtedly contribute to improving the understanding of pathologic myopia, and one specific OCT-based definition—myopic traction maculopathy (MTM), which is becoming more widely used. The clinical characteristics of MTM are becoming well defined,²⁶ and a staging system has now been proposed.²⁷ The impact of high myopia on optic nerve structure and function, as encapsulated in the term myopia associated glaucomatous optic neuropathy (MAGON) is also a topic of current research and interest.²⁸ For a detailed discussion, please refer to the IMI 2021 white paper “IMI Pathologic Myopia.”⁴

Conclusion

Standardization of myopia thresholds and definitions is improving, but much work remains to be done on this topic. Meta-analyses are now a very important aspect of myopia research, and use of consistent standards will enhance the potential of this powerful statistical approach. The field of pathologic myopia is rapidly evolving, and new classifications are likely to emerge over the coming years, led by both growing clinical interest in the topic and advances in imaging technology.

IMI DIGEST 2021—EXPERIMENTAL MODELS OF EMMETROPIZATION AND MYOPIA

The discovery of the phenomenon of form-deprivation myopia in 1977 ushered in the modern era of animal research on refractive development.³⁰ The 2019 IMI white paper on experimental models of emmetropization and myopia³¹ reviewed the significant progress that was achieved via research involving laboratory animals over the following 40+ years. Since then and through 2020, research involving animal models has continued to expand and to provide new and critical insights into factors that influence ocular growth and refractive development and that contribute to the genesis of common refractive errors like myopia. This digest highlights some of the high-interest, high-impact papers that have been published during the intervening period. The highlighted papers were selected based on a survey of the authors of the 2019 IMI experimental models paper.³² The accompanying reference list includes papers that were published since submission of the experimental models paper, specifically 3 more recent reviews,^{32–34} 3 papers that involved nonhuman primates,^{35–37} 3 that employed tree shrews,^{38–40} 14 that used chickens,^{41–54} 19 that involved guinea pigs^{55–72} and 22 that utilized mice.^{73–94} While the chicken continues to be a mainstay in experimental myopia research, the number of publications using guinea pigs and mice has increased, particularly in the latter, to take advantage of the genetic manipulations that are possible in the mouse.

Intraocular Pressure and Myopia Progression

El-Nimri NW, Wildsoet CF. Effects of topical latanoprost on intraocular pressure and myopia progression in young guinea pigs. *Invest Ophthalmol Vis Sci*. 2018;59:2644–2651.⁶⁶

Intraocular pressure (IOP) has been hypothesized to be a contributing factor to myopia progression, primarily because the biomechanically weaker scleras in myopic eyes would be more susceptible to the stretching influence of IOP. If this were true, treatment strategies that lower IOP should slow axial myopic progression. In this respect, clinical trials using the β -blocker, timolol, the only ocular hypotensive drug to be clinically tested, have yielded inconsistent results. Similarly, timolol failed to reduce the degree of form-deprivation myopia in chickens, possibly because β -blockers have minimal effects on IOP at night when myopic growth appears to dominate.

El-Nimri and Wildsoet⁶⁶ demonstrated that topical latanoprost, a prostaglandin analogue, was effective in reducing IOP over 24 hours in guinea pigs, and more importantly, this commonly used ocular hypotensive drug was effective in blocking the axial myopia produced by form deprivation. In addition, they observed that latanoprost

normalized the diurnal IOP rhythms in deprived eyes and that the observed reductions in myopic axial elongation were correlated with the magnitude of the IOP reductions, supporting a biomechanical explanation for the myopia control effects. This investigation is in agreement with a recent study by Liu et al.,⁹⁵ who showed that the α -adrenoreceptor agonist, brimonidine, which is a different class of ocular hypotensive from latanoprost, was also effective in reducing IOP and defocus-induced myopia in guinea pigs.

At present, alternative IOP-independent explanations for the actions of these drugs cannot be ruled out. Further investigations into underlying site and mechanisms of action for the myopia control effects for both latanoprost and brimonidine are needed. Nevertheless, the results of these studies are exciting because they indicate that well-tolerated, topically administered, ocular hypotensive drugs may provide a qualitatively new line of myopia control therapy.

The Role of ON and OFF Channels in Refractive Development

Wang M, Aleman A, Schaeffel F. Probing the potency of artificial dynamic ON or OFF stimuli to inhibit myopia development. *Invest Ophthalmol Vis Sci*. 2019;60:2599–2611.⁵⁴

The ON and OFF channels originate at the sign-inverting and sign-conserving synapses between the photoreceptors and the ON and OFF bipolar cells, respectively. These channels remain largely separate through the retina, the lateral geniculate nucleus, and the early stages of cortical processing. Evidence associated with genetic mutations, pharmaceutical interventions, and manipulations of the temporal luminance profiles of ambient lighting indicates that selective interruptions/adaptations of the ON and OFF retinal channels can have qualitatively different effects on normal emmetropization and vision-induced alterations in refractive development.

In this paper, the most recent in a series of papers on this topic from the Schaeffel lab, the authors investigated the effects of dynamic ON or OFF visual stimuli on choroidal thickness (CT), a predictive indicator of the direction of refractive development. In addition, they investigated the associated changes in retinal dopamine release, a key element in the signal cascade that regulates ocular growth that is dependent on ON-pathway activity. The primary findings were that in both humans and chickens, ON stimuli produced choroidal thickening, whereas OFF stimuli caused choroidal thinning. In chickens, ON stimulation also elevated dopamine release when compared to OFF stimulation. An unexpected finding in chickens was that over longer treatment periods, both ON and OFF stimulation were associated with increased myopia in response to imposed hyperopic defocus, even though relative to OFF stimulation, ON stimulation increased dopamine, a known inhibitor of myopia.

This study is noteworthy because the results show that dynamic ON and OFF local luminance stimuli have qualitatively similar effects on CT in humans and chickens. The fact that dopamine release also varied in a bidirectional manner supports the hypothesis that dopamine is involved in the CT changes produced by ON and OFF stimuli. Significantly, the direction of changes in CT produced by these dynamic luminance stimuli agreed with previous findings from the Schaeffel lab obtained in participants viewing texts of different

contrast polarities. It will be important to determine the time course for the effects of these dynamic ON and OFF stimuli because it may be possible to manipulate signals in the ON or OFF pathways in ways that are not dependent on retinal focus but that can selectively alter axial elongation rates and the progression of myopia.

Circadian Clocks and Refractive Development

Stone, RA, McGlinn AM, Chakraborty R, et al. Altered ocular parameters from circadian clock gene disruptions. *PLoS One*. 2019;14(6):e0217111.⁸⁷

Many ocular processes show diurnal oscillations that are relevant to ocular growth and refractive development. In growing eyes, axial length and choroidal thickness exhibit circadian rhythms that are altered by visual conditions that are known to interfere with normal refractive development. In animals with experimentally induced myopia, diurnal rhythms in retinal dopamine turnover and the expression of circadian rhythm-related genes are altered. The fact that manipulations of the intensity and diurnal cycle of ambient lighting, key factors in coordinating diurnal rhythms, also alter refractive development suggests that ocular circadian rhythms play a role in emmetropization and the development of common refractive errors.

In this intriguing paper, the authors investigated the effects of disrupting clock genes on optical development in 2 very phylogenetically different species, the mouse and the fly (*Drosophila melanogaster*). In comparison to littermate control mice (*Bmal1^{fl/fl}*), retinal specific knockouts for *Bmal1*, an essential component of the circadian clock, exhibited myopic refractive errors that, like common myopia in children, were associated with increases in vitreous chamber depth. In *Drosophila*, knockouts of either the *cycle* or *period* genes in the circadian clock resulted in an elongation of the fluid-filled pseudocones of the ommatidia, an optical component considered analogous to the vitreous chamber in the camera eyes of vertebrates. Thus, it appears that circadian clocks influence the pathways that regulate ocular development in both of these widely separated species.

It is known that the basic molecular mechanisms for circadian rhythms are conserved from *Drosophila* to mammals. This study demonstrates that at least some aspects of these mechanisms that play a role in regulating optical development have also been conserved across species and that the maintenance of normal ocular diurnal rhythms is fundamental to normal emmetropization. This study provides further evidence that genetic and environmental factors that influence diurnal rhythms can produce alterations in optical development of the eye that are similar in nature to those associated with common refractive errors like myopia. These findings support the idea that it may be possible to manipulate ambient lighting and societal behaviors that potentially impact circadian rhythms in ways that reduce the burden of myopia.

Contribution of Cone Pathway Signaling in Form-Deprivation Myopia

Chakraborty R, Yang V, Park HN, et al. Lack of cone mediated retinal function increases susceptibility to form-deprivation myopia in mice. *Exp Eye Res*. 2019;180:226–230.⁷³

Elegant experiments in animal models using partial diffusers have demonstrated that refractive eye growth depends on detection of visual input by the retina.^{96,97} However, the retinal signaling pathways that control refractive development and myopic eye growth remain elusive. Rod and cone photoreceptor pathways are fundamental to light detection across a large range of luminance. While there is experimental evidence that both rods and cones contribute to normal refractive development,^{98,99} cones have been thought to be more influential due to their roles in high acuity and color vision.

Chakraborty et al.⁷³ set out to investigate the role of cone photoreceptor signaling in normal refractive development and form deprivation myopia by using a mouse model with a gene mutation in *Gnat2*, the α -subunit of cone transducin. The *Gnat2^{-/-}* mice have loss of cone function with normal rod function. The authors found that the loss of cone function did not influence normal refractive development in mice. However, the *Gnat2^{-/-}* mice were more susceptible to form deprivation myopia, showing a ~65% increase in myopic shift compared to wild-type control mice after 3 weeks of goggling.

These results suggest that the retinal signaling for normal emmetropization and the response to form deprivation may not be the same. Cones were not essential for normal refractive development but significantly influenced the susceptibility to form deprivation. Interestingly, these authors have previously reported on the response of a mouse with loss of rod function, *Gnat1^{-/-}*, which showed opposite effects.^{98b} The absence of rod signaling results in a “flat” refractive development curve and unresponsiveness to form-deprivation myopia. Thus, rods and cones appear to play different roles in refractive eye growth: cones may modulate the response to form deprivation, while rods may be required to respond to form deprivation.

Importantly, these experiments take advantage of the mouse model of myopia in which genetic and environmental factors can be altered. The ability to genetically modify specific ocular cell types or pathways of interest is unique to the mouse model and provides an opportunity to examine how a given mutation alters normal refractive development across age as well as the response to myogenic stimuli. Such an approach is expected to offer new insights into the mechanisms controlling refractive eye growth and eventually to lead to new treatment targets.

Genes, Environment, and Interactions Drive Refractive Development

Tkatchenko TV, Shah RL, Nagasaki T, Tkatchenko AV. Analysis of genetic networks regulating refractive eye development in collaborative cross progenitor strain mice reveals new genes and pathways underlying human myopia. *BMC Med Genomics*. 2019;12:113.⁹¹

The increase in the prevalence of myopia is attributed to both environmental and genetic factors as well as the interplay between them. While the global rise of myopia is happening too rapidly to be solely caused by genetic factors, it is well documented that genetics play a role in the risk of developing hyperopia and myopia. As Dr. Judith Stern famously said, “Genetics loads the gun but the environment pulls the trigger,”^{99b} succinctly illustrating the idea that the interactions between genes and the environment are responsible for driving the progression of many complex diseases, such as hyperopia and myopia.

FIGURE 1. Historic overview of myopia gene finding from 1990 to 2020. Genes identified using whole exome sequencing (WES) are marked in *purple*. Other loci (linkage studies, GWAS) are marked in *red*. The cohorts used in the GWAS studies are indicated in *black*.

In this novel experiment, Tkatchenko et al.⁹¹ evaluated how genetic backgrounds of different mouse strains interact with the visual environment to affect refractive error. By tracking the refractive errors of 8 genetically different mouse strains, they uncovered differences in refractive development between strains placed in normal and myopigenic environments. To further understand why some mouse strains are more susceptible to myopia than others, Tkatchenko et al.⁹¹ performed RNA sequencing on the retinas from these strains to evaluate differential gene expression. In doing so, they identified thousands of genes and multiple pathways responsible for normal refractive development in mice, many of which overlap with findings in human studies. Intriguingly, they found that while many genes were associated with both normal refractive development and myopia susceptibility, they tended to act in opposite directions.

The integration of both phenotypic measures and transcriptomic data in this study provides a powerful approach to understanding the molecular underpinnings of refractive error development. Additionally, these findings are likely relevant for human myopia, as many of the identified biological pathways and genes are conserved across species. Overall, this study identified well-defined retinal signaling pathways that may be responsible for driving ocular growth in response to the visual environment, which could guide approaches in drug development and treatment (also see the recent review by Tkatchenko and Tkatchenko³³).

IMI DIGEST 2021—GENETICS OF MYOPIA

Introduction

Myopia is a complex disorder in which both genetic influences and environmental factors play a role. Since the first genome-wide association study (GWAS) in 2010, the number of loci associated with refractive error has increased dramatically due to larger samples sizes. Recently, over 500 loci

have been associated with refractive error (Fig. 1). The genes residing within these loci are involved in a variety of pathways, including light-processing pathways, retinal cell physiology, glutamate receptor signaling, circadian rhythm regulation, dopamine pathway, and extracellular matrix organization. Expression analyses of identified genes have implicated a role for almost all ocular cell types in the pathogenesis of myopia. While more and more loci have been associated with myopia, the exact mechanisms by which they confer susceptibility to this trait are still largely unknown. Furthermore, most of the heritability of refractive error (defined as the proportion of interindividual variation in the trait contributed by genetics) remains unexplained. Some of the missing heritability might be explained by gene–gene and gene–environment interaction, but a significant fraction of causally related genes for refractive error has yet to be discovered. There have been some key updates to the field of myopia genetics since the publication of the IMI white paper on myopia genetics.¹⁰⁰ The PubMed database was searched using various MeSH terms (e.g., “myopia/genetics,” “refractive errors/genetics,” “genetic predisposition to disease”) to identify articles published between February 2019 and April 2020. Most of these articles focused on gene-discovery in (pathologic) myopia^{101–104} the genetic overlap with myopia-related complications,^{105,106,126} epigenetics,^{78,85,107,108} transcriptomics,^{109–113} proteomics^{113,114,120} and the interaction between environmental factors and genetics.^{115,116} The key advances are highlighted below in Figure 2.

Commentary

Gene Finding. Perhaps the most important breakthrough in the past 12 months was the publication by Hysi et al.¹⁰¹ of the largest GWAS meta-analysis of refractive error to date, which included over 500,000 participants of European ancestry. This study combined data from the UK Biobank, the consumer genomics company 23andMe Inc.,

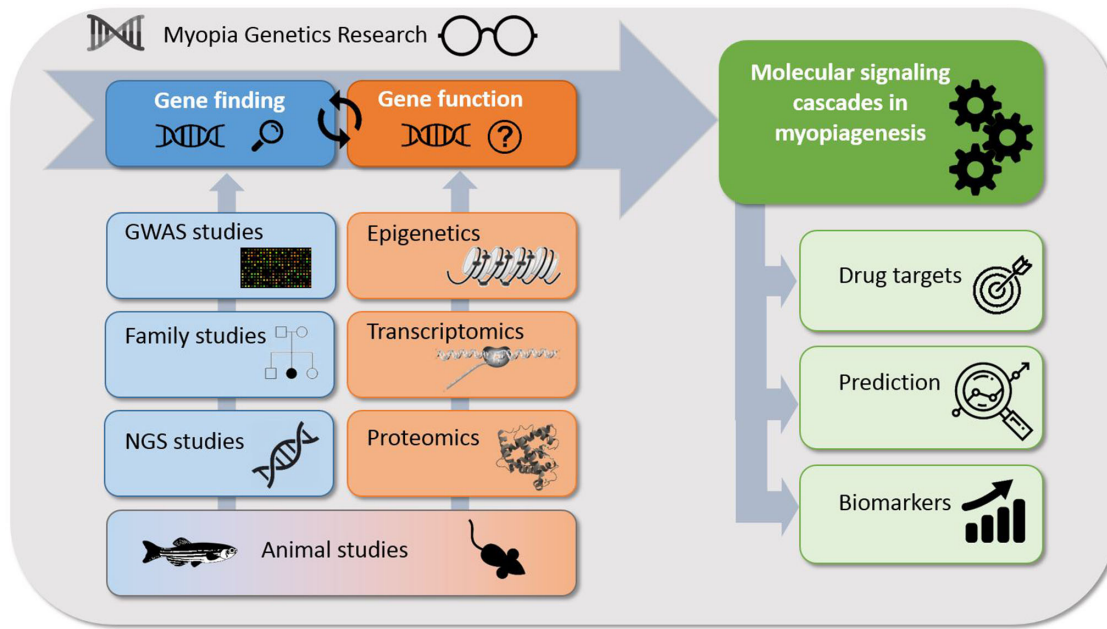

FIGURE 2. Overview of myopia genetics research.

and the Genetic Epidemiology Research on Adult Health and Aging study for discovery, along with data from the CREAM consortium for replication. The authors also carried out a meta-analysis including all studies; this meta-analysis identified 449 loci, of which 336 represented new genetic loci.

This work confirmed that refractive error is genetically an extremely heterogeneous disorder involving many different processes, genes, and ocular tissues. Among the newly identified genes are genes regulating circadian rhythm, genes with known roles in corneal dystrophies, cataract and retinal dystrophies, genes in the *Wnt* signaling pathway, and genes with prominent effects on skin, hair, and eye pigmentation. Two major sets of mechanisms were proposed by the authors: first, those affecting ocular structure, development, and physiology, including IOP, and second, central nervous system-related genes, such as those with effects on retinal signaling pathways.

In addition to gene discovery, the authors assessed whether the newly identified genetic loci could be used to detect individuals at risk of developing high myopia who could possibly benefit from intervention (e.g., at-risk individuals could be targeted for early intervention with atropine eye drops or dual-focus lenses designed to slow myopia progression).¹¹⁷ A polygenic risk score (PRS) for refractive error had an area under the receiver operating characteristics curve (AUC) of 0.75 for predicting high myopia (defined as spherical equivalent [SER] < -5.00 D), which compares favorably with previous methods for predicting myopia based on cycloplegic refraction in young children.¹¹⁸ Another genetic study similarly derived a PRS for refractive error that attained an AUC of 0.75 for predicting high myopia and found that children with a PRS in the top 10% were at 6-fold higher risk of high myopia than those in the remaining 90%.¹¹⁹ This latter study was based on a much smaller sample than Hysi et al.,¹¹¹ suggesting that there is hope for even greater accuracy in genetic prediction of myopia in the future. The genetic loci associated with myopia have relatively small effect sizes, so identifying more loci will not

necessarily improve prediction of common myopia. Nevertheless, discovering even greater numbers of genes associated with refractive error development by enlarging GWAS sample sizes and improving imputation quality and usage of alternative genetic techniques will help to further elucidate the pathogenesis of myopia.

Family Studies. One alternative technique to identify genes, and highly penetrant rare variants in particular, is to use family-based linkage studies, since any one particular causal rare variant is more likely to be observed in multiple affected individuals within a highly aggregated family than to be observed in a sample of unrelated affected individuals. Linkage analysis takes advantage of long haplotypes shared by related affected individuals and has good power to detect high-penetrance variants in large pedigrees with multiple affected individuals. Two new studies have used this approach in families from 2 founder populations in the United States, the Pennsylvania Amish¹⁰² and an orthodox Ashkenazi Jewish community.¹⁰³ In both studies, pedigrees with a strong family history of common myopia were enrolled, and exome-based microarray genotyping was performed. Participants underwent extensive eye examinations; myopia was defined as a mean spherical equivalent ≤ -1 D. An autosomal dominant model with a rare disease allele was assumed in the 2-point parametric linkage analyses. In the Amish families, genome-wide significant linkages to myopia were identified at 12q15 and 8q21.3 across all Amish families, centered on the genes *PTPRB* and *CNGB3*. *PTPRB* (a protein tyrosine phosphatase) has not been previously linked to eye disease, although other protein tyrosine phosphatases have been implicated in myopia. *CNGB3* is expressed in cones, and a genetic defect in this gene underlies achromatopsia. Further, 3 genome-wide significant linked variants were also found within a single Amish family. These variants were all located in the gene *SLC618*, which would be novel for eye disease. In the Ashkenazi families, genome-wide significant linkage signals, not previously associated with eye disease, were observed on 7q36.1 and

8q24, centered on the genes *SSPO* and *WISP1*. This data set also replicated a previously published linkage on 1p36.1. Since linkage peaks are broad, the genes with the strongest evidence for linkage above may not be causal. Genome-wide sequencing of the most informative families in these data will help identify the causal genes and variants.

Epigenetics. Individuals who develop myopia early in life have a higher likelihood of progressing to high myopia. This may be caused by myopia genes with expression and effect early in life. Another explanation of this effect might be related to epigenetic changes due to influences in utero. Furthermore, epigenetic changes might influence myopia development in childhood or even between generations. Only a few studies have focused on epigenetic changes—those possibly influenced by early environmental factors—in myopia development.

An epigenome-wide association study by Seow et al.⁸⁵ aimed to find CpG methylation sites in umbilical cord tissue associated with early onset myopia. A study population of 519 Malay, Indian, and Chinese children with available umbilical cord blood and SER at 3 years was included for analysis (29 cases [SER < -0.50 D] and 490 nonmyopic controls). Epigenetic signals were evaluated at 160,418 separate loci after adjusting for ethnicity, sex, gestational age, cellular composition, and batch effects. Five CpG probes (*cg21880079*, *cg14066632*, *cg03155767*, *cg17154092*, *cg26299044*) showed evidence of association with myopia; all were hypomethylated in myopia cases compared to controls (2.81% to 4.49% methylation change in cases compared to controls). Adjusting for parental myopia and smoking did not materially change the results. One of the 5 sites was located in a known myopia locus (*MYP10*) and 4 of the probes could be annotated to genes (*ARL1*, *FGB*, *PQCL1*, *KRT12*). *ARL1*, *PQCL1*, and *KRT12* showed expression in both fetal and adult human ocular tissue, whereas the *FGB* gene showed significant scleral expression in ocular mouse tissue. The authors considered that all 4 genes might be involved in corneal epithelium development and membrane transport. Umbilical cord blood was used to investigate the methylation profile. Therefore, these results may help in predicting early onset myopia but may not fully reflect biological changes in ocular tissue. The authors, however, suggest that the biological changes seen in early onset myopia in very young children are already reflected in umbilical cord tissue at birth. In addition, differentially methylated CpG sites may be used as biomarkers to predict high myopia in children. Replication in a larger data set and examination of the correlation between umbilical cord tissue methylation and eye tissue are warranted to strengthen the evidence.

A second epigenetic study by Williams et al.¹⁰⁷ examined DNA methylation at approximately 450,000 CpG sites across the genome of 921 children of European ancestry from the United Kingdom (ALSPAC study), using cord blood samples collected at birth and peripheral blood samples collected at age 7 and 15 years. The capacity of these 450,000 epigenetic probes to predict myopia at age 7 and 15 years was assessed using 10-fold cross-validation. The AUC for predicting myopia at age 7 years was significantly better than at age 15 years ($P = 0.001$), with an AUC in the range of 0.60 to 0.64. Detailed analysis of 9 prescreened genes (*APLP2*, *RASGRF1*, *GJD2*, *ZMAT4*, *LAMA2*, *RBFOX1*, *TSPAN10*, *DRD1*, *CASC15*) previously implicated as being imprinted or involved in gene–environment interactions were tested for enriched CpG sites whose methylation

level was associated with myopia at age 7 or 15 years. This revealed an association of myopia at age 7 years with DNA methylation at CpG site *cg13403566* near *RASGRF1* (uncorrected $P = 6.4 \times 10^{-5}$; Bonferroni-corrected $P = 0.025$). The authors demonstrate stronger links of early epigenetic marks with myopia at age 7 years rather than age 15 years in the context of an intriguing observation that the prevalence of myopia at age 7 years (but not 15 years) was lower if the paternal grandmother had smoked in pregnancy. This association was primarily found among grandsons compared to granddaughters. Smoking is one of the best-known environmental exposures affecting epigenetic profiles, and several examples of adverse or adaptive “transgenerational” inheritance carried by epigenetic marks have been documented in humans and animal models.¹⁰⁷

Vishweswaraiah et al.¹⁰⁸ studied epigenetic differences in 18 children aged 4 to 12 years with a high degree of myopia (SER ≤ -6 D) and 18 healthy controls from 1 Polish center. The authors identified 1541 CpG sites in 1745 unique genes with a 2-fold or higher differential methylation in the high-myopia cases compared to controls. Methylation was assessed using the EPIC array (with some 850,000 CpG) probes from peripheral blood. The study of more extreme cases may be a powerful approach, but on the other hand, the small sample size means that firm conclusions cannot be made and replication in much larger samples is needed. Epigenetic mechanisms can also be explored using animal models, which enable use of the relevant tissues.

Liang et al.⁷⁸ successfully used this strategy; their study was based on the hypothesis that *HOXA9* plays a role in myopia development similarly to other established homeobox genes associated with myopia (*PAX6* and *MEIS1*). Moreover, *HOXA9* is known to transcriptionally activate the well-known myopia-associated transforming growth factor β (TGF- β) signaling cascade. In the Growing Up in Singapore Towards Healthy Outcomes birth cohort study, 8 preschool children represented refractive error outliers (SER < -2 D), and 7 of them had hypomethylation at *HOXA9*, suggesting that overexpression of *HOXA9* could be a risk factor for early onset myopia. The researchers then performed animal studies, measuring *HOXA9* RNA levels in the retina of form deprivation myopia (FDM) mice ($n = 9$) by real-time polymerase chain reaction (PCR). These levels in the retina of myopic eyes were significantly higher ($P = 0.029$, paired t -test) than of the uncovered fellow eye. Lastly, the cellular studies based on murine retinal pigment epithelium (RPE) cells demonstrated that an increase of *HOXA9* could increase expression in several myopia-associated genes, including TGF- β , *FGF2*, *IGF1R*, and *MMP2*. The authors concluded that since *HOXA9* is a transcription factor, it may directly or indirectly affect expression of myopia-associated genes. Albeit an elegant approach, there remains the need for replication, a larger sample size, analyses on human eye-related tissue, and bulk testing of multiple genes.

Transcriptomics (MicroRNAs). Regulatory mechanisms have been implicated in myopiagenesis.¹²¹ While there are many regulatory elements, such as enhancer RNAs, long noncoding RNAs, and microRNAs (miRNAs), most studies focused on miRNAs for their potential therapeutic role or as a clinical biomarker. Several studies have performed miRNA next-generation sequencing and quantitative PCR (qPCR) on human aqueous humor derived at onset of cataract surgery or refractive surgery between highly myopic versus nonmyopic eyes. Zhu et al. detected differential expression between 249 mature miRNAs and 17 novel miRNAs in

myopic eyes (age range 19–67 years) compared to control eyes (age range 55–89 years). The authors postulated that the TNF, MAPK, PI3K-Akt, and HIF-1 signaling pathways might be regulated by these miRNAs. A subset of miRNAs was confirmed by qPCR (hsa(homo sapiens)-let-7i-5p, hsa-miR-127-3p, and hsa-miR-98-5p).¹⁰⁹ Chen et al.¹¹⁰ focused on exosomal miRNA profiles in aqueous humor and their role in myopia development (n = 16 patients; 8 myopia (age range 57–71 years) and 8 control (age range 57–87 years). These exosomal miRNAs are likely involved in the pathogenesis of various eye diseases. The researchers found that the numbers and sizes of exosomes were not significantly different between the myopia and control group. The individual exosomes of the same group were pooled to purify RNA. Unexpectedly, the myopia group contained 2.78-fold more RNA than that in the control group: 15 miRNAs were myopia specific, and 4 miRNAs were absent in the myopia group. Six well-known myopia-associated genes (*CHRM2*, *CNGB3*, *VEGFA*, *ADORA2A*, *IGF1* and *LUM*) were identified as potential targets for 5 myopia-specific miRNAs (hsa-miR-582-3p, hsa-miR-17-5p, hsa-miR-885-3p, hsa-miR-19b-3p, and hsa-miR-450b-5p).

Two reports on the novel topic of miRNA expression in low-dose atropine treatment (0.003%) against myopia development were published.^{111,112} Both studies focused on gaining more insight into the molecular mechanism of atropine on myopia treatment and defending the safety of low-dose atropine treatment, using either human scleral fibroblasts¹¹² or human corneal epithelial cells.¹¹¹ Hsiao et al.¹¹² identified slight changes in scleral gene expression after 0.003% atropine treatment, supporting the safety of low-dose atropine treatment. This study revealed the association of *hsa-miR-2682-5p-KCNJ5* and *hsa-miR-2682-5p-PRLR* with scleral growth repression and circadian rhythm. Chang et al.¹¹¹ analyzed the messenger RNA (mRNA) and miRNA expression profiles between atropine-treated and control corneal epithelial cells. They found that low-dose (0.003%) atropine was associated with dysregulation of certain genes. Several bioinformatics tools predicted that this dysregulation might suppress the apoptosis of the corneal epithelial cells, potentially through Ras and protein kinase A signaling pathways. Hsa-miR-651-3p-*EPHA7*, hsa-miR-3148-*TMEM108*, and *hsa-miR-874-5p-TBX6* were validated as possible miRNA regulators of mRNA dysregulation (i.e., miRNA-mRNA interaction) involved in corneal epithelial cells treated with 0.003%. Although the findings of these studies give more insight into the molecular mechanisms of atropine treatment, the results should be replicated using larger studies and similar human eye-related tissues. Moreover, studies should include the entire range of doses in atropine treatment, since there is a clear dose-effect relationship between atropine and axial elongation.^{122,123}

Proteomics. One important question is how differences in genetic background, miRNA expression, and methylation translate to changes in protein expression and how this relates to the development of myopia and pathologic myopia. Currently, most studies focusing on proteomics followed a candidate gene approach using vitreous humor. Wei et al.¹¹³ investigated differences in protein expression in vitreous humor of pathologic myopia (myopes with retinal detachment [RD], macular hole, epiretinal membrane, or retinoschisis) compared to healthy eyes (SER > -6.00 D and axial length < 26.5 mm without any chorioretinal degeneration) and discovered differences in levels of 2 antioxidative proteins (PGDS, GPX3). Ding et al.¹²⁰ used vitreous humor

of patients with vitreomacular interface disease as a control group and discovered differences in expression of *CTGF* and *HGF* in these patients compared to high-myopia patients. A candidate gene study from Peng et al.¹¹⁴ found elevated levels of *DKK1*, involved in the canonical Wnt/ β -catenin pathway, in the vitreous humor of pathologic myopia eyes. These proteins could be potential drug targets for myopia prevention treatments.

Animal Models. Previous work has demonstrated an overlap between myopia susceptibility in humans and animal models.^{42,104} Regarding myopia pathways across species and identification of major pathways, Tkatchenko et al.⁹¹ examined normal refractive error development and susceptibility to form-deprivation myopia using RNA sequencing in 8 distinct mouse strains. An extensive review of this publication can be found in this IMI 2021 yearly digest section on experimental models. In short, the gene sets controlling baseline refractive development and those regulating susceptibility to myopia overlapped, but these 2 processes appeared to be controlled by largely distinct sets of genes. The authors suggest that regulation of emmetropization may be different from pathways that modulate environmental influences, such as optical defocus, and only a subset of the genes controls both processes. An alternative explanation, derived from a chick study, suggests that genes controlling normal variation in eye size are distinct from genes conferring susceptibility to form-deprivation myopia.¹²⁵ Furthermore, Tkatchenko et al.⁹¹ performed a genome-wide gene-based association analysis in the CREAM consortium and UK Biobank human cohorts to identify mouse genes and pathways associated with myopia in humans. They identified that 985 differentially expressed mouse genes were associated with myopia in humans, of which 847 were newly reported associations and need validation in humans. However, the authors did not clarify if such a large number of genes could have been found simply by chance. Nevertheless, investigating the consistency of findings from animal studies and human genetic studies is a promising approach for elucidating the causal mechanisms of the trait.

Shared Genetic Background Between Myopia and Other Eye Diseases. Myopia is well known to be associated with various complications such as RD, or primary open angle glaucoma (POAG). It was unsurprising that several genetic loci associated with refractive error overlapped with significant RD risk loci.¹⁰⁵ A more interesting aspect was the nature of those loci: *BMP3* and *ZC3H11B* were among the replicated RD risk loci, suggesting that myopia-related pathways, such as eye elongation control, may be more pertinent to RD risk than others. The authors also remarked that *PRSS56*, which strongly associated with high myopia, did not appear to impact RD. Together with GWAS for other myopia-associated conditions and traits, RD GWAS will help to better understand myopia heterogeneity and associated loci function. Risk of detachment seemed to increase steadily with increasing polygenic myopia risk score (PRS) population quintile—a risk score the authors derived from a small fraction (n = 71) of significant variants from the previous CREAM refractive error GWAS¹²¹—both for clinically ascertained rhegmatogenous RD and for a less well-defined set of retinal detachments from the UK Biobank.

The study by Han et al.¹⁰⁶ examined the RD-myopia link in a formal Mendelian randomization (MR) framework, which can provide evidence for causality. MR studies can

be thought of as “natural RCTs,” with the randomization coming from the random assortment of alleles at conception. The MR design can help avoid problems such as confounding and provide genetic support for a causal link. By using genetic data from the UK Biobank, Han et al.¹⁰⁶ showed that there is likely to be a causal link between myopia and RD, with each 6-D decrease in refractive error leading to a 7.2-fold increase in RD risk. By leveraging our understanding of myopia genetics, knowledge about RD pathogenesis is also increased, enabling the possible identification of potential targets for prevention of RD in general and RD in myopes.

The clinical association between myopia and POAG has been studied extensively. However, it was unclear whether these 2 complex conditions share a common genetic background. Iglesias et al.¹²⁶ aimed to quantify the degree of genetic overlap between myopia and POAG (and POAG endophenotypes) in an Australian/New Zealand (the Australian & New Zealand Registry of Advanced Glaucoma study) and Dutch population-based cohort (the Rotterdam Study). PRSs were derived and the genetic correlation between myopia and POAG, IOP, vertical cup to disc ratio, cup area, disc area, and retinal nerve fiber layer was assessed using a technique known as linkage disequilibrium score regression analysis. Surprisingly, genetic predisposition to myopia did not predict POAG status in either population. In fact, evidence of a shared genetic architecture was only found between myopia and optic disk area, which is in line with previously found associations between refractive error and optic disk size.^{124,127,128} Nevertheless, concluding that there is no clear genetic association between myopia and POAG, the authors were careful to point out that the relatively small sample size and the challenge of diagnosing POAG in myopic eyes were limiting factors. Interestingly, MR in the largest GWAS to date, described above, showed that higher IOP causes more negative spherical equivalent (more myopia) in the general population, and this might explain the previously suggested relationship between myopia and glaucoma.¹⁰¹

Breaking Developments

The results from the largest GWAS meta-analysis to date for refractive error confirmed that this approach continues to yield new discoveries as sample sizes increase.¹⁰¹ As well as providing opportunities to better understand the mechanisms regulating myopia development via the discovery of novel genes and pathways, these studies also offer potential new targets for treatment of myopia and myopia progression.

The widespread availability of omics data enables new discoveries in the field of myopia genetics.^{78,85,107–114,120} As discussed, 3 human epigenetic myopia studies were published in the past year.^{85,107,108} Epigenetics might allow greater understanding of how the environment causes myopia but may require prospective longitudinal studies to investigate changes of methylation signatures during life. In healthy volunteers, we are usually limited to data from blood. Epigenetic signals can be tissue specific; therefore, studies should ideally be performed on samples of retina, choroid, and sclera. Tissue samples taken during surgery for other conditions may be a possible source. However, in the absence of such samples, the studies above demonstrate a role for surrogate tissues in the identification of biomarkers.

Finally, another significant development was the joint analysis of data from animal models and human studies,⁹¹ which highlights the possibility of strengthening the

evidence and gaining new insights on novel pathways by combining these data. In addition to finding new myopia loci, future research should focus on understanding the molecular signaling cascade leading to myopia. Defining particularly the crucial steps in myopia pathogenesis will help in discovering new potential molecules for targeted intervention.

Conclusions

With increasing sample size of studies and new genetic analysis techniques such as whole-genome sequencing and gene–environment interaction analysis, we will find more genetic loci in the future to explain the missing heritability for refractive error. Genetic vulnerability to myopic complications such as myopic macular degeneration or RD as well as genetic susceptibility to a positive response to treatment should be the focus of future research as these have immediate clinical impact. Furthermore, examining prenatal and intergenerational influences on myopia development, such as in the previously described epigenetic studies, is a first step to explain how the environment has an impact at an early stage in life. Methylation analysis and RNA sequencing data are valuable approaches, but the limited availability of ocular tissue restricts widespread use in humans at this moment.

For now, the great challenge of our field is to unravel the pathophysiologic pathways from the current known genetic loci. Next steps should be aimed at understanding how these myopia genes contribute to certain biological processes, how they interact together, and how they are influenced by environmental factors, such as lifestyle. Subsequently, when more insight is gained in the function of these genes, they may be a starting point for new treatment options and prevention strategies.

IMI DIGEST 2021—INTERVENTIONS FOR CONTROLLING MYOPIA ONSET AND PROGRESSION

In a survey conducted in 2018 to 2019, eye care practitioners in many countries were found to be concerned about the problem of myopia, yet most were not actively intervening to slow myopia. Unfortunately, while 80% of practitioners agreed that single-vision (SV) spectacles or under-correction was not effective in slowing myopia, some 4 years later, approximately 64% continued to prescribe SV refractive corrections, citing increased cost and inadequate information as the reasons.¹³⁰ Nonetheless, the search for myopia control treatment has continued since the intervention white paper in 2019,¹³¹ with studies over the intervening period largely focused on understanding and improving the efficacy of treatments. In this update, we summarize recent advances for myopia control in relation to specially designed spectacle and contact lens devices; topical atropine, which remains the only pharmacologic treatment option; and some novel intervention strategies. This update is largely limited to already completed clinical trials.

Specially Designed Multiple Segment Focal Spectacles

There is just 1 new study to report. In a 3-year prospective, randomized, multicenter clinical trial, 600 myopic schoolchildren (age: 6 to 12 years, myopia: -1.00 to -4.00 D) were randomized to wear either a novel multifocal

cal lens design (defocus-incorporated multisegment [DIMS]) or SV lenses.¹³² The DIMS lens has a central distance optical zone, with an annular peripheral zone incorporating multiple small segments of positive power (~ 1.03 mm in diameter, $+3.50$ D), with the goal of imposing myopic defocus on local peripheral retinal regions. At the end of the first 2 years of this trial, myopia progression in the DIMS lens-wearing group was significantly reduced relative to that of the SV lens group; myopia increased by -0.38 ± 0.06 vs. -0.85 ± 0.08 D (expressed as spherical equivalent refraction [SER]), and axial lengths increased by 0.21 ± 0.02 vs. 0.56 ± 0.02 mm, respectively. These results represent improved efficacy over previously tested multifocal spectacle lens designs. This multisegment spectacle lens design is currently also being trialed in northern China, although no results are yet available.¹³³

Specially Designed Multifocal Contact Lenses

Three recent trials not only confirmed that it is feasible to slow myopia with optical interventions, but like the specially designed multisegment spectacle lens study, these trials also reported substantially greater slowing of myopia than in most previous trials.^{132,134,135}

One of these trials, a 3-year, multicenter, double-masked, randomized clinical trial, involved the MiSight 1 day (ScottsVille, NY) contact lens, which was compared with SV contact lens. Both lenses were prescribed on a daily wear, daily disposable basis.¹³⁴ Participants comprised 144 children, aged between 8 and 12 years, with low to moderate myopia (-0.75 to -4.00 D). Over the 3-year trial period, myopia progressed by -0.51 ± 0.64 vs. -1.24 ± 0.61 D (expressed as SER) and axial lengths increased by 0.30 ± 0.27 D vs. 0.62 ± 0.30 mm, representing a greater than 50% reduction in progression with MiSight by both indices.

The second randomized clinical trial involved 508 children, assigned to wear 1 of 4 test contact lenses; 2 were based on an extended depth of focus principle, and 2 were novel multifocal designs that imposed myopic defocus on both central and peripheral retinal regions. SV daily disposable lenses were included as the control reference.¹³⁵ As in the case of the MiSight lens trial, both changes in refractive errors and axial lengths over 2 years were significantly lower in the groups wearing test lenses, ranging from -0.78 to -0.87 D (SER) and 0.41 to 0.46 mm compared to -1.15 D (95% confidence interval [CI], -0.99 to -1.30) and 0.60 mm (95% CI, 0.53 to 0.66 mm) in the SV lens group. Interestingly, the rates of progression across the 4 test contact lenses were not significantly different, and improved efficacy was also linked to better wearer compliance in the case of the test lenses.

The third trial was a 3-year, double-masked clinical trial of 294 children with myopia randomized to wear soft center-distance multifocal lenses with either a medium or high add ($+1.50$ vs. $+2.50$ D) or an SV soft contact lens.¹³⁶ The choice of multifocal contact lens design aimed to provide clear central vision while simultaneously focusing some light in front of the retina to slow eye growth. The 3-year adjusted myopia progression (SER) was -1.05 D with the SV contact lenses compared to -0.60 and -0.89 D with the high and medium add multifocal lenses, respectively. The slowed myopia progression apparent in the refractive error data is mirrored in the smaller axial length increases in the high and medium add groups over the same period, of 0.42 and 0.58 mm, respectively, compared to 0.66 mm for the SV group. Nonetheless, differences in progression between the

multifocal and SV lens groups reached statistical significance only for the high add group. Also, unlike other reports,¹³⁵ longer wearing times were not found to enhance the treatment effect.

Orthokeratology

Research seeking to both understand the mechanism underlying the myopia control effect of orthokeratology (OK) and improve its effectiveness is also ongoing. In one such retrospective longitudinal study of 103 subjects,¹³⁷ both total higher-order aberration root mean square and spherical aberrations were found to be significantly and positively correlated with axial length and negatively correlated with axial elongation. Further studies are warranted to follow up on the possibility that spherical aberration plays a key role in the OK myopia control effect, as suggested by these data.

Although not specifically addressing the issue of myopia control efficacy in relation to OK, one other OK study worthy of mention monitored 66 children (6 to < 16 years) wearing SV spectacles for 7 months before switching them to OK for another 7 months.¹³⁸ All children displaying rapid axial elongation were found to benefit from OK, with younger children (< 9 years), who tended to show more rapid axial elongation compared to older children, benefiting most. On the basis of these results, the authors suggested monitoring progression for a period of time (3–6 months) before intervening with OK, to ensure that the benefits from the intervention outweighed the risks of serious adverse events, given that OK is also a costly, time-consuming intervention option.

Topical Atropine

In relation to topical atropine for myopia control, important new findings since the 2019 white paper relate to (1) concentrations and (2) combination therapies. Late 2019 saw the publication of results of phase 2 of the Low-Concentration Atropine for Myopia Progression (LAMP) study.¹³⁹ Phase 1 involved daily treatment of children (4 to 12 years, at least 1.00 D myopia) with 0.01% , 0.025% , or 0.05% atropine, with a placebo treatment also included. In phase 2, 383 of the 438 participants in phase 1 continued their originally assigned treatments, with the exception of the placebo group, which was switched to 0.05% atropine. Over the 2-year trial period, increases in myopia for the 0.05% , 0.025% , and 0.01% concentrations were 0.55 ± 0.86 D, 0.85 ± 0.73 D, and 1.12 ± 0.85 D, respectively, and increases in axial lengths, 0.39 ± 0.35 mm, 0.50 ± 0.33 mm, and 0.59 ± 0.38 mm, respectively. Myopia progression (based on both indices) in the placebo group decreased with the switch to 0.05% atropine for the second year of the trial. For both the 0.05% and 0.025% concentrations, treatment effects were comparable across both years. The overall treatment effect with the 0.01% concentration lagged behind the 0.025% and 0.05% concentrations, which were also both well tolerated. Note that both this study and the well-known ATOM series of clinical trials involved East Asian sites. As atropine is known to bind avidly to melanin, with pigmented ocular tissues serving as a local reservoir, it will be of interest to compare these published data with results from other ongoing clinical trials of low-concentration atropine, such as The Childhood Atropine for Myopia Progression in the UK study (CHAMP)^{147b} and the Myopia Outcome Study of Atropine in Children (MOSAIC).¹⁴⁸ Both of these trials involve multiple sites distributed throughout United States and Europe, with

much higher representations of Caucasian children, who typically have less heavily pigmented ocular tissues than East Asian children.

Results from a retrospective study and early findings from a clinical trial combining topical 0.01% atropine with OK lenses were also published in 2019. The underlying premise of combination therapies is that overall treatment efficacy can be improved, assuming that complementary rather than shared mechanisms underlie each of the treatment effects. In one retrospective study,¹⁴⁰ 60 children undergoing OK were found to benefit from the addition of nightly 0.01% atropine in the second year; axial elongation dropped from 0.46 ± 0.16 mm in the first year to 0.14 ± 0.14 mm, irrespective of age and refractive error, although those showing the fastest progression in year 1 appeared to benefit most. However, it should be noted that those who refused atropine treatment were not included in the analysis as controls; instead, the authors used a group of historical controls ($n = 29$) whose axial elongation was significantly different from their test group (0.35 ± 0.11 mm) after 1 year of OK lens wear ($P = 0.0013$). Nonetheless, these results are consistent with results from an earlier, smaller-scale study¹⁴¹ and a closely related 2-year clinical trial involving 59 myopic children (6 to 11 years, -1.00 to -4.00 D).¹⁴² In the latter study, the children were fitted with OK lenses, 29 of whom also used 1 drop of 0.01% atropine nightly prior to insertion of their lenses. Significantly less axial elongation was recorded in those using the combination therapy (0.07 ± 0.16 vs. 0.16 ± 0.15 mm; $P = 0.03$) at the end of 12 months. Lens performance was also reported to be unaffected with 0.01% atropine use in this study. Recommendations on the value of combining topical atropine with therapies involving multifocal manipulations must await further data, although the apparent enhancement of the effect of imposed myopic defocus on the peripheral retinal induced component of multifocal ERG recording by topical 0.1% atropine is intriguing.¹⁴³

Environmental Influences and Novel Treatments

While spending more time outdoors has been shown to have therapeutic benefit, as reported in the early intervention white paper, the mechanism underlying this protective effect remains to be resolved. While there are no new studies to report here, the ongoing interest in novel treatments for myopia and on refractive error development more

generally can be assessed indirectly through filed patents (NCT03538002 and NCT03623074; clinicaltrials.gov); also, there are ongoing trials related to environmental and optical interventions, although no published clinical data are currently available.

IMI Digest 2021—Clinical Myopia Control Trials and Instrumentation

The 2019 IMI—Clinical Myopia Control Trials and Instrumentation report reviewed the prospective evidence base from existing myopia control trials of at least 1 year in duration along with the supporting academic literature. The review yielded recommendations on the design of future clinical trials for determining the effectiveness of treatments at slowing myopia progression and the impact of these treatments on patients. Since the publication of the first series of the IMI white papers to the end of 2019, 2 papers have been published on spectacle interventions,^{133,144} 3 on soft contact lens trials (1 being an extension of an existing cohort),^{134,135,145} 1 orthokeratology study,¹⁴⁶ 4 on the effect of administering atropine,^{147–150} and 2 trials of combined atropine and soft contact lenses¹⁵⁰ or OK.¹⁵¹

Participant Inclusion

These trials have all used cycloplegic refraction with participant selection criteria of a maximum astigmatism from -0.75 D to -2.50 D (generally higher for atropine studies), maximum anisometropia of 1.00 to 1.50 D (although not reported in several studies), minimum distance visual acuity from 20/20 to 20/25, a minimum age from 6 to 8 years (although 1 study included participants as low as 4 years of age), and a maximum age typically between 11 and 13 years (although 2 studies recruited children up to 15–16 years of age) (Table 3). Recruiting patients with high astigmatism could lead to them having a very different optical environment (such as an increased depth of focus),¹⁵² making it more difficult to evaluate the myopia intervention. The progression of childhood myopia slows with age, so including 15- to 16-year-old children in a trial that lasts several years will reduce the apparent effectiveness of the intervention when considering the actual reduction in eye growth in millimeters or increase in myopia measured in diopters.

TABLE 3. Selection Criteria in Recent Myopia Control Clinical Trials

Author, Year	Intervention	SER, Min to Max (D)	Cycloplegia	Ast Limit (D)	Aniso Limit (D)	VA Min	Age, Min to Max, y
Kanda et al., 2018 ¹⁴⁴	Spectacle (novel plus design)	-4.50 to -1.50	Y	1.50	1.50	20/20	6 to 12
Lam et al., 2020 ¹³²	Spectacle (novel plus design)	-5.00 to -1.00	Y	1.50	1.50	20/20	8 to 13
Li et al., 2019 ¹⁴⁶	OK	-4.00 to -1.00 (sphere)	N?	1.50	NR	20/20	8 to 15
Ruiz-Pomeda et al., 2018 ¹⁴⁵	SCL (concentric bifocal)	-4.00 to -0.75	Y	1.00	1.00	20/25	8 to 12
Chamberlain et al., 2019 ¹³⁴	SCL (concentric bifocal)	-4.00 to -0.75	Y	0.75	1.00	20/25	8 to 12
Sankaridurg et al., 2019 ¹³⁵	SCL (multifocal and novel design)	-3.50 to -0.75	Y	0.75	NR	20/30	7 to 13
Walline et al., 2020 ¹³⁶	SCL (multifocal +1.50 and +2.50 add)	-5.00 to -0.75 (sphere)	Y	1.00	2.00	20/25	7 to 11
Azuara-Blanco et al., 2019 ^{147b}	Atropine (0.01%)	-10.00 to -0.50	Y	2.00	NR	20/32	6 to 12
Joachimssen et al., 2019 ¹⁴⁷	Atropine (0.01%)	NR	NR	NR	NR	NR	6 to 17
McCrann et al., 2019 ¹⁴⁸	Atropine (0.01%)	-1.00 or more myopic (least myopic meridian must be -0.50 or more myopic)	Y	2.50	NR	20/32	6 to 16
Yam et al., 2019 ¹⁴⁹	Atropine (0.01%, 0.025%, 0.05%)	-1.00 or more myopic refraction	Y	2.50	NR	NR	4 to 12
Huang et al., 2019 ¹⁵⁰	SCL (multifocal) plus atropine (0.01%)	-5.00 to -0.75 sphere	Y	1.00	2.00	20/25	7 to 11
Tan et al., 2019 ¹⁵¹	OK plus atropine (0.01%)	-4.00 to -1.00	Y	2.50	1.00	20/25	6 to 11

Aniso, anisometropia; Ast, astigmatism; N, no; NR, not reported; SCL, soft contact lens; VA, visual acuity; Y, yes; ?, unclear.

It should be noted that if reporting treatment effects as a percentage reduction, enrolling older children could yield a falsely higher increased apparent efficacy, as discussed later. Enrolling older children also adds additional complexities such as the necessity of exclusion criteria such as “negative pregnancy test for females with childbearing potential,”¹⁴⁸ as was done in one such trial. In addition to the previously recommended participant selection criteria,¹⁶ several studies also limited ethnic diversity,^{132,152} the maximum amount of myopia (either due to optical correction availability or increased risk of pathology), birth term/weight,¹³⁴ and specifically excluded connective tissue disorders such as Marfan and other more general systemic pathology.^{135,152} One study required at least 1 parent to be myopic.¹⁴⁴ Two studies required a threshold amount of myopia progression over the past year as an inclusion criterion,^{149,150} despite the previously identified issues with such an entry criterion including the variability of subjective refraction, determining progression based on just 2 data points, and the lack of standardization of the refraction when extracting retrospective data from a chart review. None of these differences in recently published studies would appear to warrant revision to the previously recommended participant selection criteria of:

Inclusions.

Refractive error	Cyclopleged spherical or SER myopia of at least −0.75 D
Astigmatism	≤1.00 D
Anisometropia	≤1.50 D
Age	6–12 years
Visual acuity	20/20 minimum

Exclusions.

History	Previous rigid lens wear or myopia control treatment
Ocular disease	Any (other than myopia)
Binocular vision	Anomaly
Systemic disease	Those that may affect vision, vision development, or the treatment modality
Medications	Those that may affect pupil size, accommodation, or have an impact on the ocular surface

If these criteria are not followed, the apparent efficacy of a treatment may be underestimated and it may be more difficult to compare approaches across studies.

Study Design

Most of these studies have followed their cohort for 2 years (Table 4), with an additional year to examine whether there was any rebound in 2 of the atropine studies and in the second year in one of the spectacle studies. All studies have shown a reduced effectiveness of treatments in the second year, demonstrating why more than 1 year of follow-up is needed to assess the long-term efficacy of the treatment. The extrapolation of a 1-year treatment effect to multiple years (an approach taken by many myopia calculators, for example) can lead to incorrect conclusions. Hence, the prior IMI recommendation of a 3-year minimum length (plus an addi-

tional year of no treatment to examine any rebound effect) of a clinical trial assessing the efficacy of a treatment for myopia control is still upheld. All new studies, except one on orthokeratology, appropriately applied masking and randomization; however, stratification of subjects is rare. Appropriate controls have been selected for the control group, although Tan et al.¹⁵¹ did not include a placebo drop in their orthokeratology alone control group, which could have identified those patients in the treatment group who used atropine drops in addition to orthokeratology.

One ethical dilemma that is now being discussed is the appropriateness of including a control group in studies. If the treatment is well enough established to slow or prevent myopia progression, is it ethical to randomly assign subjects to an ineffective sham/control group given their likelihood to develop myopia or have myopic progression? The decision to include a control group rests on whether treatments with a similar risk profile are well enough established to be recommended (as previously indicated by the IMI clinical trials report)¹⁶ or not (as indicated for all therapies except for atropine by a recent Cochrane systematic review¹⁵³ and as is advocated by some professional bodies).¹⁵⁴ Another consideration is whether there should be triggers within the rebound examination year to reinstate treatment if myopia progression seems to accelerate after discontinuing the active treatment. This issue is problematic as eye growth varies by season throughout the year and thus is not linear; therefore, determining whether there has been an acceleration in eye growth is difficult without a full year's observation. There is also the issue as to whether good comparative control data on myopia progression in children already exist in the academic literature that can serve as a suitable historical control for any cohort of children recruited to study a new intervention. Progression differs by age, ethnicity, and season and has been hypothesized to vary depending on environmental factors such as outdoor time or light levels¹⁶; therefore, it is difficult to argue that a historical control can be expected to adequately represent, without bias, the progression one would expect with a randomized control group. Hence, our assessment is that, at present, an appropriately selected concurrent control group is still ethical for myopia control trials, along with an additional full year of no treatment in the treated group, to assess any rebound effect.

Outcome Measures

The outcomes of myopia progression clinical trials can still be classified as primary (refractive error and/or axial length), secondary (patient-reported outcomes and treatment compliance), and exploratory (peripheral refraction, accommodative changes, ocular alignment, pupil size, outdoor activity/lighting levels, anterior and posterior segment imaging, and tissue biomechanics).¹⁶ However, visual disturbances (reported subjectively such as halos and glare or measured objectively such as with halometry) and patient-reported outcomes have been further specified in the minimum data set for different modalities of treatment (Table 5).

It has been recently questioned at relevant conferences whether the slowing of myopia progression should be reported as a percentage, as has been traditionally done, or as an absolute/cumulative reduction in myopia progression (in diopters) or slowed axial elongation (in millimeters) between a treatment and control group. This issue has arisen due to the reduction in treatment efficacy over time

TABLE 4. Control Group, Randomization, and Masking of Recent Myopia Control Trials

Author, Year	Intervention	Control	Rando- mization	Strati- fication	Masking	Initial Study Length, y	Rebound Assessment
Kanda et al., 2018 ¹⁴⁴	Spectacle (novel plus design)	Spectacle (SV)	Y	N	Y	2	N
Lam et al., 2020 ¹³²	Spectacle (novel plus design)	Spectacle (SV)	Y	N	Y	2	N
Li et al., 2019 ¹⁴⁶	OK	Spectacle (SV)	N	N	N	1	Y (1 month)
Ruiz-Pomeda et al., 2018 ¹⁴⁵	SCL (concentric bifocal)	Spectacle(SV)	Y	Y	N	2	N
Chamberlain et al., 2019 ¹³⁴	SCL (concentric bifocal)	SCL (SV)	Y	Y	Y	3*	Y (planned) [†]
Sankaridurg et al., 2019 ¹³⁵	SCL (multifocal and novel design)	SCL (SV)	Y	N	Y	2	N
Walline et al., 2020 ¹³⁶	SCL (multifocal +1.50 and +2.50 add)	SCL (SV)	Y	Y	Y	3*	Y (planned) [†]
Azuara-Blanco et al., 2019 ^{147b}	Atropine (0.01%)	Placebo	Y	N	Y	2	N
Joachimssen et al., 2019 ¹⁴⁷	Atropine (0.01%)	None	N	N	N	1	N
McCann et al., 2019 ¹⁴⁸	Atropine (0.01%)	Placebo	Y	Y	Y	3	Y (study year 3)
Yam et al., 2019 ¹⁴⁹	Atropine (0.01%, 0.025%, 0.05%)	Placebo (year 1 only)	Y	Y	Y	3	Y (study year 3)
Huang et al., 2019 ¹⁵⁰	SCL (multifocal) plus atropine (0.01%)	Historical (SCL SV and SCL multifocal)	N	N	N	3	N
Tan et al., 2019 ¹⁵¹	OK plus atropine (0.01%)	OK only	Y	N	Y	2	N

SV, single vision.

TABLE 5. Expected Minimum Data Set for Each Treatment Modality

Treatment Modality	Distance Visual Acuity	Near Visual Acuity	Contrast Sensitiv- ity	Pupil Size	Cycloplegic Refrac- tion	Axial Length	Amplitude of Accom- modation	Visual Distur- bances	Lens Centration	Wearing Time	Instillation Compli- ance	Patient- Reported Outcomes
Spectacles	X	X	X	X	X	X	X	X		X		X
Soft multifocal contact lenses	X	X	X	X	X	X	X	X	X	X		X
Orthokeratology	X	X	X	X	X	X	X	X	X	X		X
Pharmaceuticals	X	X	X	X	X	X	X	X			X	X

during a trial, which is presumed to be due to the increasing age of the children. Another issue with percentages is that they depend on the rate of progression in the control group; the same absolute effect size when reported as a percentage will appear larger or smaller depending on whether there is slower or faster myopia progression in the control group. It has also recently been suggested that perhaps only a maximum amount of myopia can be prevented by a treatment, regardless of treatment duration. Reporting the overall slowing of myopia progression or axial growth between the treatment and control group seems to be a sensible suggestion; therefore, we would advocate the reporting of both a percentage and absolute amount of reduced myopia progression/axial elongation in future clinical trial reports.

Instrumentation

New instrumentation relevant to myopia progression trials includes exploratory outcome devices to objectively monitor working distance¹⁵⁵ and light levels to assess key environmental factors. A new aberrometer that utilizes pyramidal optics (as opposed to Hartmann–Shack aberrometers) for measuring ocular aberrations has been developed and validated on model eyes¹⁵⁶ and in humans¹⁵⁷ as repeatable and accurate. Choroidal OCT and angiography have been used to explore differences in structure and function of this tissue, particularly in high myopes.^{158,159}

Conclusion

Clinical trials for myopia control must be carefully designed to inform clinical practice and to better understand the mechanism of action of treatments to allow further refine-

ments. Some recently published studies still do not include fundamental elements, such as masking and randomization, a simultaneous control group, and clearly defined enrollment criteria to minimize bias and the potential to report inaccurate conclusions. The original 2019 IMI white paper¹⁶ and this update can be used by researchers and industry to inform their clinical trial design. This information can also be used by clinicians and regulatory bodies to interpret the strength of evidence provided by published trials and to compare risks and benefits between treatments.

IMI DIGEST 2021—CLINICAL MANAGEMENT GUIDELINES FOR MYOPIA

The intent of this Yearly Digest is to highlight significant additions to the clinical management of myopia since the publication of the 2019 IMI white paper on clinical management guidelines.¹⁶⁰ This review takes into account publications on new interventions and key understandings of the myopia management landscape, which have influenced how science is translated into practice.

Several notable randomized controlled studies on myopia control interventions have been published since early 2019. While examining the detail of these intervention studies is not the remit of the Yearly Digest, the impact of these studies on clinician awareness of myopia control options and how this has influenced clinical management must be noted. First, 2 new contact lens studies marked a departure from traditional multifocal contact lens designs, typically prescribed for presbyopia, to myopia control-specific designs. The MiSight 3-year¹³⁴ and extended depth of focus 2-year¹³⁵ randomized controlled contact lens studies presented robust evidence of efficacy to slow both axial and

TABLE 6. Summary of Results for Recently Published Myopia Control Intervention Studies

Intervention Study	Duration, y	Absolute Difference in Progression Between Treatment and Control Groups	
		Refractive (D)	Axial Length (mm)
MiSight contact lens ¹³⁴	3	0.66	0.28
Extended depth of focus contact lens ¹³⁵ (4 designs tested)	2	0.27 to 0.37 (across 4 test designs)	0.14 to 0.19 (across 4 test designs)
Biofinity +2.50 contact lens ¹³⁶	3	0.45	0.23
DIMS spectacle lens ¹³²	2	0.44	0.34
LAMP atropine ¹⁴⁹			
0.01%	1	0.22	0.05
0.025%		0.35	0.12
0.05%		0.54	0.21

Differences between adjusted means are presented as detailed in each paper.

refractive myopia progression. Second, the Defocus Incorporated Multiple Segments (DIMS) spectacle lens 2-year study¹³² revealed perhaps the strongest efficacy results of all spectacle lens interventions, arguably similar to that of contact lens designs. As well, the Bifocal Lenses in Near-sighted Kids group demonstrated a significant slowing of axial length and refractive error with the CooperVision-Biofinity +2.50 D add but not the +1.50 D add lenses in a 3-year randomized trial¹³⁶ (discussed in Interventions for controlling myopia onset and progression). Finally, the LAMP 1-year study¹⁴⁹ provided a control group comparison that importantly highlighted the concentration-dependent success of atropine intervention, which had been unclear from previous studies. The absolute differences in refractive and axial length outcomes between treatment and control groups in these studies are provided in Table 6. The sum total of these studies provides clarity in intervention evidence and, in combination with increasing availability of the optical treatments, leads to improved prescribing options for childhood myopia.

As clinicians have also begun combining atropine with optical interventions, 2 randomized controlled trials are currently under way. Recently reported 2-year data on combining atropine 0.01% with orthokeratology showed no benefit for children who had more than 3 D and less than 6 D of myopia at baseline, but 0.11 mm less total axial elongation in myopes of 1 to 3 D at baseline.¹⁶¹ There was no correlation between age and efficacy of the combined treatment.¹⁶¹ Baseline data for bifocal soft contact lenses combined with 0.01% atropine have also been presented.¹⁴⁹

The remit of the Clinical Management Guidelines report was to canvas all aspects of patient identification, communication, clinical tests, and guidelines for management. Four newly published papers describe the current landscape of myopia control research and practice, as well as key depictions of the risk-to-benefit balance to assist clinicians in understanding and communicating the imperative for myopia management.

Myopia Control 2020: Where are We and Where are We Heading? Bullimore MA, Richdale K. *Ophthalmic and Physiological Optics* 2020;40:254–270¹⁸

This review highlighted key outcomes of recent peer-reviewed literature. Original spectacle lens studies employing progressive addition and traditional flat-top bifocals reported no clinically meaningful results, limiting their

uptake by clinicians; however, novel spectacle designs such as those developed by Hong Kong Polytechnic University (DIMS) and SightGlassVison are reporting myopia control results approaching that of contact lens designs. Likewise, symptoms and rebound associated with 1% atropine were not considered clinically acceptable, and 0.01% showed little efficacy in controlling axial elongation. The recent LAMP study demonstrated excellent tolerability and efficacy with 0.05% atropine and, based on current research, it is arguably the optimal concentration with which to initiate treatment. Advances in these modalities provide safe and effective treatment options for children not ready for or interested in contact lenses. Children as young as 7 to 8 years of age can successfully wear contact lenses. The longest myopia control data available to date, a single orthokeratology study, demonstrate a myopia control effect of 0.45 mm over 7 years of wear. The 2 recent soft contact lens trials show excellent 2- and 3-year efficacy in controlling progression (Table 6). Approval for myopia control varies broadly by country and may influence practitioner and parental decisions on treatment.

There is no valid progression-based criterion for initiation of myopia control. Age is the single most important factor in predicting progression—with younger children typically progressing more quickly—but ethnicity, sex, and parental history of myopia also influence progression. The vast majority of children with myopia will progress, and thus parents should be educated about treatment and management options as soon as a child develops myopia. The only caveat to treating all children with myopia is that some may be considered to have “pathologic” myopia, such as those developing myopia before the age of 5 years, or in association with a systemic condition. There is no research to suggest that standard myopia control treatments will be effective in these cases. Parents should also be educated to anticipate that myopia control treatment should be continued until myopia stabilizes, which is expected to be in the later teens or early 20s. Future research is aimed at maintaining high safety standards while further improving efficacy of single and combination treatments.

International Survey of Contact Lens Fitting for Myopia Control in Children; Efron N, Morgan PB, Woods CA et al. *Contact Lens and Anterior Eye* 2020;43:4–8¹⁶²

Childhood myopia requires correction as well as control; contact lens interventions show the best propensity for

achieving both as a monotherapy. Uptake of contact lens fitting for myopia control (MC) in children was evaluated in a serial survey. The proportion of pediatric contact lens fits for MC increased from 0.2% of all fits in 2011 to 6.8% in 2018. This trend is mostly attributable to increase in rigid lens fitting for MC, particularly since 2016. Rigid lens fits for myopia control have increased from only a few percent of all rigid lens fits in 2011 to over 20% from 2016 to 2018, now representing over half of all MC fits but only 12% of all non-MC fits.

Variation by country in the proportion of pediatric contact lens (CL) fits for MC ranged from over 20% of all fits in Austria, Germany, and Hong Kong to no fits in the Czech Republic, Japan, South Korea, and Puerto Rico. Across the 31 countries surveyed, children fit for MC are on average younger (mean 13 years) compared to non-MC fits (mean 15 years); 84% wear their lenses 7 days per week compared to 56% of non-MC fit children.

This survey indicates that despite increases in education and research, clinical application of contact lenses for childhood myopia control is still low. Moreover, the average age for MC fits in this survey is higher than ideal, given that intervention at a younger age (before age 12) is indicated to achieve the greatest myopia control effects.¹⁶⁰ The authors cited international differences in the extent of CL fitting for MC as due to specific lens availability, along with practitioner training, attitudes, and confidence. Overall low uptake was described as likely due to lack of on-label products for most of the survey period and in most parts of the world, uncertainty about efficacy, and lack of awareness among parents of MC benefits. As these data were truncated prior to publication of the IMI Clinical Management Guidelines, it is hoped that future prescribing surveys will indicate a continued upward trend in myopia control contact lens fits to children, along with a downward trend in mean age.

Childhood and Lifetime Risk Comparison of Myopia Control With Contact Lenses; Gifford KL. Contact Lens and Anterior Eye 2020;43:26–32¹⁶³

Barriers to pediatric contact lens prescribing can include concerns about safety. To address this, the short-term risk of pediatric contact lens wear for myopia control was compared to the lifetime risk of myopia-associated pathology. This analysis determined that the comparative risk of microbial keratitis (MK) across a lifetime of any type of contact lens wear, when presumed to commence at age 8 for myopia control, is less than the lifetime risk of vision impairment with myopia more than 6 D or axial length more than 26 mm. Childhood contact lens wear risks were calculated over 10 years of wear—from age 8 to 17 inclusive. When added to these childhood risks, a lifetime of contact lens wear was modeled by calculation of 47 years of adult contact lens wear (age 18 to 65 years inclusive) plus 10 years of no contact lens wear (from 66 to 75 years inclusive). Peer-reviewed data on infection risk in various contact lens wear modalities were compared to published cumulative risk of vision impairment by age 75.

The findings indicated that 10 years of pediatric overnight orthokeratology wear—the “riskiest” type of myopia control contact lens wear in childhood—presents a 1 in 66 likelihood of MK, compared to a 1 in 33 lifetime risk of vision impairment with myopia of 0.5 to 3.0 D. The “riskiest” way to wear contact lenses over a lifetime was modeled to be 10 years of

childhood reusable soft contact lens wear on a daily schedule with 47 years of adult soft contact lens extended wear, presenting a 1 in 7.7 lifetime risk of MK. When compared to lifetime risks presented by myopia to an individual, the risk of vision impairment is 1 in 3.9 for eyes 26 to 28 mm long and 1 in 5 for eyes with 6 to 10 D of myopia. Myopia under 3 D and axial lengths less than 26 mm make a lifetime of orthokeratology or reusable soft contact lens wear more risky by comparison, while a lifetime of daily disposable wear presents a 1 in 76 risk of MK, which is less than any of the calculated myopia risks.

These findings provide scientific basis for clinicians to be proactive in recommending myopia control contact lenses to younger children, as both the short-term safety profile and long-term preventative eye health benefits are evident.

Myopia Control: Why Each Diopter Matters; Bullimore MA, Brennan NA. Optometry and Vision Science 2019;96:463–465¹⁶⁴

While keeping myopia below 6 D and axial length less than 26 mm through myopia control intervention is a key goal, the value of the smaller goal of 1 D of control is perhaps the strongest clinical message to emerge since publication of the IMI Clinical Management Guidelines. Three arguments for the advantages of 1 D lower myopia are presented. First, less visual disability while uncorrected and the relationship to quality of life were explored. As stated by the authors, “Corrected or not, greater refractive error produces greater disability and dependence on whatever mode of correction [is] used.”

Second, improved availability and better visual outcomes for future surgical myopia correction were described. Laser in situ keratomileusis has been demonstrated to reduce best-corrected low-contrast acuity in higher myopes, and higher ablations can increase risk of postoperative ectasia. Finally, this important analysis demonstrated that across the range of refractions, each 1 D less of final myopia translates to 40% less lifetime risk of developing myopic maculopathy, which is the most common and serious sight-threatening complication of myopia. This was compared to the Age-Related Eye Disease Study for age-related macular degeneration (ARMD), which found a 25% risk reduction in progression to advanced ARMD through years of administration of antioxidants plus zinc. When viewed similarly as a preventative eye health treatment, and that most myopia control interventions pose low relative risk, reducing an individual’s final level of myopia by 1 D presents a clear public health imperative for reducing future visual impairment for millions of myopes around the world. The authors note that while research continues on treatment options and their absolute efficacy, and long-term data are lacking, it is reasonable to speculate that currently available myopia control interventions could provide a cumulative treatment effect of 1 D. This simple perspective on what is a complex field provides the clinical “why” for proactive myopia management.
